Abstract. Determining the timing and extent of Quaternary glaciations around the globe is critical to understanding the drivers behind climate change and glacier fluctuations. Evidence from the southern mid-latitudes indicates that local glacial maxima preceded the global Last Glacial Maximum (LGM), implying that feedbacks in the climate system or ice dynamics played a role beyond the underlying orbital forcings. To shed light on these processes, we investigated the glacial landforms shaped and deposited by the Lago Argentino glacier (50° S), an outlet lobe of the former Patagonian Ice Sheet, in southern Argentina. We mapped geomorphological features on the landscape and dated moraine boulders and outwash sediments using ¹⁰Be cosmogenic nuclides and feldspar infrared stimulated luminescence (IRSL) to constrain the chronology of glacial advance and retreat. We report that the Lago Argentino glacier lobe reached more extensive limits prior to the global LGM, advancing during the middle-to-late Pleistocene, between 243–132 ka, and during Marine Isotope Stage 3 (MIS 3), culminating at 44.5±8.0 ka and at 36.6±1.0 ka. Our results indicate that the most extensive advance of the last glacial cycle occurred during MIS 3, and we hypothesize that this was a result of longer and colder winters, as well as increased precipitation delivered by a latitudinal

migration of the Southern Westerly Winds belt, highlighting the role of local and regional climate feedbacks in modulating ice mass changes in the southern mid-latitudes.

1 Introduction

15 Unraveling the timing of continental ice sheet growth and decay is crucial for determining glacier response to climate forcings and feedbacks within the Earth's system. However, our understanding of the climatic drivers behind global glacier change is limited by the availability of highly resolved past glacial records. For instance, Northern Hemisphere insolation intensity has been proposed to pace the climate of the Southern Hemisphere during the last million years, implying synchronous ice sheet growth and decay across hemispheres every ~ 100 ka, coincident with the eccentricity cycles of the Earth's orbit (Abe-Ouchi et al., 2013; Hays et al., 1976; Imbrie et al., 1993). Nonetheless, evidence indicates that glaciers in mid-to-high latitudes in the Southern Hemisphere expanded prior to the global Last Glacial Maximum (LGM, 26.5–19 ka; Clark et al., 2009), suggesting that other mechanisms, apart from the underlying orbital parameters, could have played a role in inducing pre-LGM glacier growth, such as local ice dynamics, ocean-atmosphere interactions, and latitudinal shift of the Southern Westerly Winds (SWW; Fig. 1A; Darvill et al., 2015, 2016; Denton et al., 2021; Doughty et al., 2015; García et al., 2018; Hall et al., 2020; Mendelová et al., 2020; Shulmeister et al., 2019).

Since glacial chronologies are necessary to determine the timing and occurrence of glacial expansions and recessions, dating glacial deposits provides a first order constraint on past glacier fluctuations. In South America, evidence indicates that the Patagonian Ice Sheet (PIS) expanded during the last glacial cycle (115–11.7 ka; Hughes et al., 2013), reaching its maximum extent between 35–28 ka in northern sites and around 47 ka in southern sites (Davies et al., 2020). The PIS formed a continuous ice sheet along the spine of the Andean Cordillera from 38°S to 55°S (Fig. 1B), with a sea level equivalent of approximately 1.5 m (Davies et al., 2020; Hulton et al., 2002)

Lago Argentino (Fig. 1B) is located on the eastern flank of the Southern Patagonian Icefield and constitutes the largest ice-contact lake in the world, with multiple lake-terminating glaciers calving into it (Van Wyk de Vries et al., 2022). Lago Argentino drains to the east into the Río Santa Cruz basin and, ultimately, the Atlantic Ocean. Given that during the LGM the western margin of the PIS reached the sea (Davies et al., 2020), fewer moraines are preserved in the terrestrial geological record. In contrast, glacial landforms in the arid eastern foreland of the Andes are better preserved due to lower weathering rates, in response to the rain shadow effect imposed by Andean Range (Garreaud et al., 2009), making moraines located in the Argentine steppe more suitable for geochronological dating. Despite well-dated glacial records for the Lago Argentino and Río Santa Cruz basin during the Plio-Pleistocene (Clague et al., 2020; Mercer, 1976; Strelin and Malagnino, 1996; Strelin et al., 1999) as well as during the Late Glacial and Holocene (Kaplan et al., 2011; Strelin et al., 2011, 2014), the middle-to-late Pleistocene glacial history of the Lago Argentino glacier lobe, an outlet lobe of the former PIS, remain largely unstudied.

To fill this data gap on the age and extent of the Lago Argentino glacier lobe for the remainder of the Pleistocene and to improve the understanding of glacial cycles in the Southern Hemisphere during this period, we produce a new highly resolved geomorphological map of the upper basin of the Río Santa Cruz, date moraine-crest boulders with cosmogenic nuclide surface

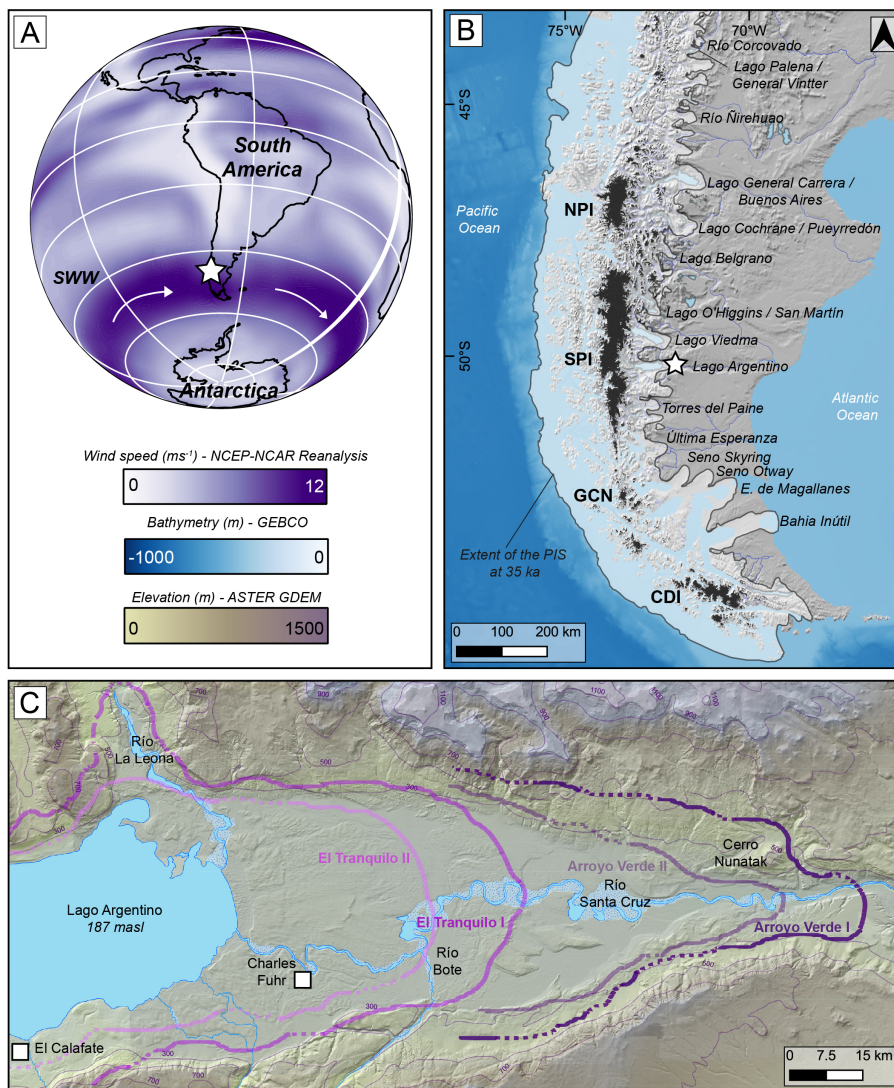

Figure 1. (A) Location of study site in a hemispheric context along with Southern Westerly Winds (SWW) speed data at 850 mb after Kalnay et al. (1996), (B) Ice extent of the former Patagonian Ice Sheet (PIS) at 35 ka (Davies et al., 2020) along with major outlet lobes, topographic hillshade, bathymetry data, and ice bodies: Northern (NPI) and Southern (SPI) Patagonian Icefields, Gran Campo Nevado (GCN), and Cordillera Darwin Icefield (CDI). The white star denotes the location of the study site (Lago Argentino glacier lobe), (C) Digital Elevation Model (DEM) of the upper basin of Río Santa Cruz located eastward of Lago Argentino. Shades of purple indicate the defined (solid lines) and inferred (dashed lines) of the middle-to-late Pleistocene glacial limits (Strelin and Malagnino, 1996, 2009).

45 exposure dating, and date proglacial outwash using feldspar Infrared Stimulated Luminescence (IRSL). We report the extent of the Lago Argentino glacier lobe during the late Quaternary, and show that the maximum ice extent during the last glacial cycle occurred during Marine Isotope Stage 3 (MIS 3; 57–29 ka; Lisiecki and Raymo, 2005), preceding the Northern Hemisphere

glacial maximum that occurred during MIS 2 (MIS 3; 29–14 ka; Lisiecki and Raymo, 2005). Therefore, this dataset highlights the PIS sensitivity to local and regional climate feedbacks and provides an improved understanding of the landscape evolution of the Lago Argentino basin during the Pleistocene.

2 Background

2.1 Physical setting

The Río Santa Cruz valley ($\sim 50^\circ$ S) runs ~ 250 km from the easternmost end of Lago Argentino to the Atlantic Ocean. Late Miocene to early Pliocene basaltic plateaus bound it to the north and south (Ramos and Kay, 1992). These plateaus are underlain by early to middle Mesozoic marine and fluvial sedimentary successions (Casadio et al., 2000; Goyanes and Massabie, 2015). The upper sector of this valley consists of a broad plain (Fig. 1C) that narrows ~ 65 km east of the lake's margin, where glacial landforms are present (Strelin and Malagnino, 1996).

The drainage basin surface area is about 30×10^3 km², where river length is ~ 385 km with a maximum modern water discharge of ~ 1200 m³/s in March, while minimum discharge values are measured in September (~ 300 m³/s, Pasquini et al., 2021). Discharge has increased in the Lago Argentino basin throughout the 21st century due to rapid and accelerating ice loss on the eastern flank of the icefields (Van Wyk De Vries et al., 2023). The SWW deliver the bulk of the precipitation from the west in a predominant SW-NE direction (Fig. 1A), with greater summer intensity (Garreaud et al., 2009). In a similar seasonal fashion, ice melt rates and glacier velocity reach their maximum during the summer (Minowa et al., 2017, 2021; Mougnot and Rignot, 2015). Precipitation is abundant on the west of the Andean range and reaches annual values of between 5000-10000 mm, but the semiarid terrain around Lago Argentino receives less than 200 mm per year (Garreaud et al., 2013; Lenaerts et al., 2014).

2.2 Glacial history and previous studies

Several authors have contributed to the understanding of the local landscape evolution, even though no chronological evidence is available for the middle-to-late Pleistocene glaciations. During his journey to South America, Darwin (1842) discussed the possible glaciomarine origin of erratic boulders in the Río Santa Cruz basin. The first geomorphological assessment was carried out by Caldenius (1932), who identified four distinct moraine belts, and according to their preservation state, assigned relative ages based on the Fennoscandian glaciations (De Geer, 1927). Caldenius (1932) named these moraine systems (from eastern outer to western inner) Initioglacial, Daniglacial, Gotiglacial, and Finiglacial.

Based on this framework and new observations, different authors assigned Caldenius' Finiglacial moraines to the Last Glaciation, and the outer moraines complexes to the early and middle Pleistocene glaciations (Feruglio, 1944; Strelin and Malagnino, 1996; Strelin et al., 1999; Strelin and Malagnino, 2009; Rabassa and Clapperton, 1990; Wenzens, 1999, 2005). Mercer (1976) provided one of the first geochronological constraints by dating lava flows overlying glacial deposits, and

determined the easternmost glaciations occurred during the Pliocene and early Pleistocene at 3.5–1.5 Ma. These results were supported by additional dating carried out in the vicinity of Lago Viedma and Lago Argentino (Clague et al., 2020).

80 Strelin and Malagnino (1996, 2009) mapped and described glacial deposits and provided the first geomorphological map with its associated stratigraphy. They proposed that five glaciations occurred in the upper Río Santa Cruz basin and named them (from eastern outer to western inner) Estancia La Fructuosa, Chuñi Aike, Cerro Fortaleza, Arroyo Verde, and El Tranquilo. For this work, we only focus on the Arroyo Verde and El Tranquilo moraines, as identified by Strelin and Malagnino (1996). These authors interpreted that the Lago Argentino glacier lobe deposited the Arroyo Verde I and II moraines at one of the
85 narrowest points of the valley, and then El Tranquilo I and II moraines, located closer to the lake's margin (Fig. 1C). Based on a morphostratigraphic approach, they suggested that the Arroyo Verde I and II moraines were deposited during the Penultimate Glaciation, and that a large proglacial lake developed after the glacier receded. Later, they suggested that El Tranquilo I and II moraines could have been deposited during the last glacial cycle, but without the geochronology necessary to confirm this. Lastly, Strelin and Malagnino (1996, 2009) suggested that the Lago Argentino glacier lobe readvanced and deposited the
90 Puerto Banderas moraines westwards of El Tranquilo moraines. The latter are known to date from the Antarctic Cold Reversal, deposited about 10 km from the modern ice front at ~13,000 cal yrs before present (Strelin et al., 2011).

3 Methods

3.1 Geomorphological mapping

We built on previous mapping efforts and geomorphological studies carried out in the vicinity of the upper basin of Río Santa
95 Cruz to create a new, detailed geomorphological map of the Arroyo Verde and El Tranquilo glaciations over an areal extent of ~2000 km² (Strelin and Malagnino, 1996; Strelin et al., 1999; Strelin and Malagnino, 2009). We identified landforms remotely using a 5 m resolution aerial-photogrammetry-derived digital elevation model (DEM) provided by the Instituto Geográfico Nacional of Argentina (IGN) and an orthomosaic of the area (pixel = 40 cm). We complemented these using Google Earth satellite imagery and ASTER GDEM. We conducted field validation during 2019 and 2020 to complement the remote
100 sensing and verify initial geomorphological interpretations (Chandler et al., 2018). We assessed glacial landsystems by performing sedimentary and stratigraphic loggings around the major landforms, and then manually digitized the geomorphological features using ArcMap 10.5 and QGIS, where we created both polygons and polylines to delineate the landforms. We followed previously published criteria (Cooper et al., 2021; Leger et al., 2020; Mendelová et al., 2020; Peltier et al., 2023; Soteres et al., 2020, 2022), and we classified these features based on their primary depositional environment as ice marginal (e.g.,
105 moraines, hummocks), subglacial (e.g., glacial lineations, drumlins), glaciofluvial (e.g., outwash plains), glaciolacustrine, and other non-glacial features (such as modern hydrography). Lastly, we used built-in geospatial tools to derive the count, length, and orientation of the mapped topographic features.

3.2 Geochronological dating

3.2.1 ^{10}Be cosmogenic nuclide surface exposure dating

110 We determine the age of moraine abandonment (therefore, culmination of ice advance) by using ^{10}Be cosmogenic nuclide
surface exposure dating on moraine boulders. We targeted boulders from the Arroyo Verde and El Tranquilo moraines, as
defined by Strelin and Malagnino (1996). We sampled eighteen quartz-bearing boulders of 0.5–4 m in height, deposited across
three different moraine complexes (i.e., Arroyo Verde II, El Tranquilo I, El Tranquilo II). We targeted subrounded boulders
lacking erosional features (e.g., pitting) to avoid removal of nuclides due to post-depositional processes, and sampled those
115 exposed on moraine crests. We collected approximately 1.5–2 kg from flat surfaces using a hammer and a chisel. We report the
location (latitude, longitude, elevation) of the sampled boulders using a handheld GPS with a vertical uncertainty of < 10 m.
We account for topographic shielding using a GIS-based toolbox (Li, 2013, 2018) on the DEMs employed for mapping (see
section 3.1). We provide field and analytical information in Table 1.

We processed the samples for ^{10}Be extraction at the University of Wisconsin-Madison following standard laboratory pro-
120 cedures (Ceperley et al., 2020; Jones et al., 2023), using a ^9Be carrier solution prepared from raw beryl (OSU White, ^9Be
concentration = 251.6 ± 0.9 ppm; Marcott, 2011). $^{10}\text{Be}/^9\text{Be}$ ratios were measured at the Purdue University Rare Isotope Mea-
surement Laboratory (PRIME Lab) and normalized to standard 07KNSTD, which has an assumed $^{10}\text{Be}/^9\text{Be}$ ratio of 2.85×10^{12}
(Nishiizumi et al., 2007). Lastly, we background-corrected the ^{10}Be concentrations with batch-specific blank values (Table 1,
S2).

125 We calculated exposure ages using Version 3 of the CRONUS-Earth online calculator (last accessed October 20th, 2023;
Balco et al., 2008), employing a local production rate developed for the Late Glacial chronology at Lago Argentino ($3.71 \pm$
 0.11 atoms/g/yr; Kaplan et al., 2011). We did not apply snow correction to our ages given the low precipitation levels in the area
today, and we considered a rock density of 2.65 g/cm^3 . As part of a sensitivity test, we calculated the ages with different erosion
rates for all landforms, ranging from 0.2–1.4 mm/ka according to Douglass et al. (2006) and Kaplan et al. (2005), respectively,
130 with the latter representing a maximum erosion rate. Since the outcomes of using different erosion rates (Table S1, Fig. S6)
do not change the main results of this work and given that age differences overlap within analytical uncertainties, we use an
erosion rate equivalent to zero for all the samples for our reported ages and interpretations. Here, we report the calculated ages
using the time dependent scaling (Lm: Lal, 1991; Stone, 2000), the non-time-dependent scaling (St: Stone, 2000; Lal, 1991),
and the LSDn scaling scheme developed by Lifton et al. (2014). Even though we account for different scaling schemes listed
135 in Table 2, the choice of the scaling scheme (LSDn) does not impact our interpretations. We report the age of each moraine
complex in the text as the computed mean and standard deviation (Table 2). Lastly, we employ the iceTEA toolbox to plot age
distribution and to identify outliers (Jones et al., 2019).

3.2.2 Feldspar infrared stimulated luminescence (IRSL) dating

We collected four proglacial sediment samples and two loess samples to date the timing of outwash and aeolian deposition
140 using infrared stimulated luminescence (IRSL, Table 3, Table S3). Luminescence approaches, including optically stimulated

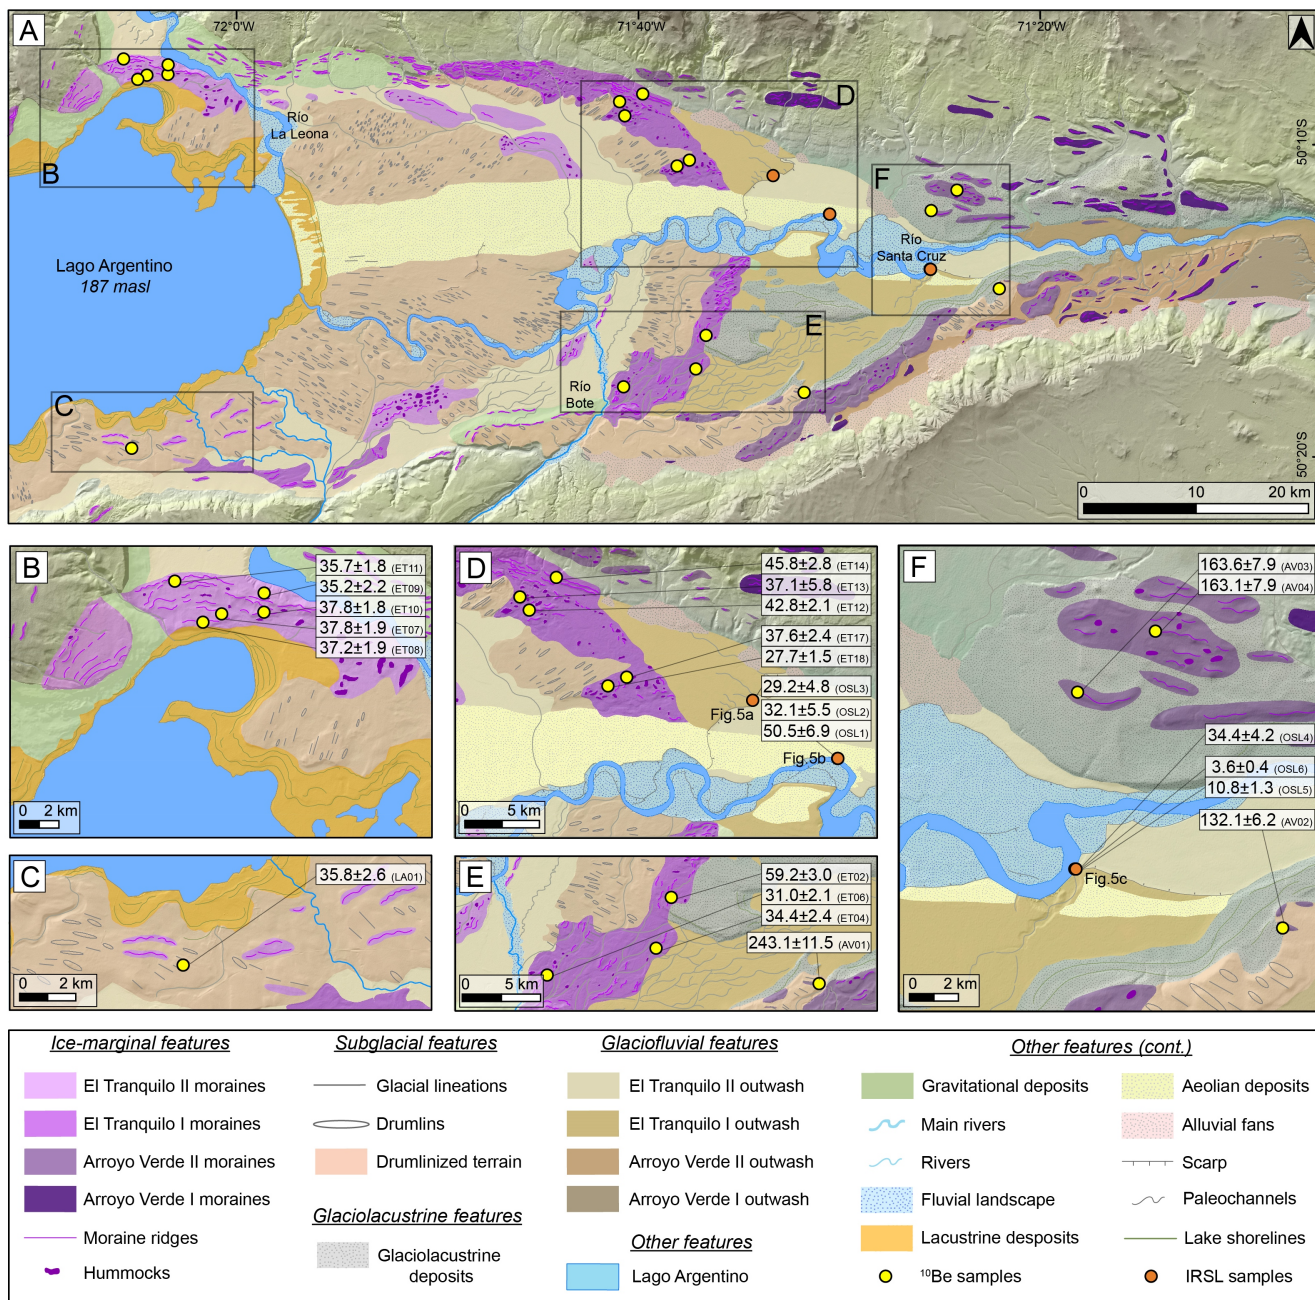

Figure 2. (A) Quaternary geomorphological map of the main glacial landforms in the upper Río Santa Cruz basin (Fig. 1C): ice marginal (moraines, hummocks), subglacial (drumlins, lineations), glaciolacustrine, glaciofluvial (outwash plains), as well as other features. Panels (B–F) are close views of the mapped landforms along with geochronological results denoting the age in thousands of years (kilo annum, ka) with 1σ analytical uncertainty of the boulder sampled (yellow circles). Luminescence samples (orange circles) are associated with their corresponding profile on Fig. 5.

luminescence (OSL) and IRSL are well-suited to date the timing of deposition and subsequent burial of sediment grains. While other studies in Patagonia have been able to use quartz grains and OSL dating in glaciogenic sediments (Smedley et al., 2016), due to poor quartz quality and paucity in the local lithology of Río Santa Cruz, we used feldspar grains and IRSL to date these sediments, as previously performed in other glacial settings in Patagonia (Blomdin et al., 2012). We carried out sample collection according to established field procedures published by Nelson et al. (2015) using opaque aluminum tubes, opaque plastic caps, and a rubber mallet. We processed the samples at Utah State University Luminescence Laboratory following standard procedures involving sieving to 150-250 μm , HCl and H_2O_2 treatments to remove carbonates and organics, heavy mineral separation at 2.58 g/cm^3 with no HF pre-treatment, to isolate the potassium-rich feldspar component. The IRSL signal was measured on 1-2 mm aliquots ($\sim 20\text{--}50$ grains) at 50°C according to the single-aliquot regenerative-dose (SAR) procedures for potassium feldspar dating (Wallinga et al., 2000). Measurements were performed on Risø TL/OSL Model DA-20 readers with infrared light-emitting diodes (LEDs, 870 ± 40 nm, ~ 120 mW/cm^2) and signals were detected through a blue filter pack of 2-mm and 4-mm thick filters (BG-39 and Corning 7-39, respectively). IRSL ages were corrected for fading (loss of signal with time; Huntley and Lamothé, 2001; Auclair et al., 2003) and reported using the central and minimum age models (CAM and MAM; Galbraith and Roberts, 2012) based on skew in the aliquot data indicative of partial bleaching (see figure S7 in supplemental data for radial plots). Samples for dose-rate determination were collected in sediments surrounding the sample tube and analyzed for elemental concentration using ICP-MS and ICP-AES techniques. These concentration values were converted to dose rate following the conversion factors of Guérin et al. (2011) and beta attenuation values of Brennan (2003) using the DRAC on-line dose-rate calculator (Durcan et al., 2015). The beta dose included contribution from 12.5% internal potassium and 400 ppm Rb and an a-value of 0.086. Contribution of cosmic radiation to the dose rate was calculated using sample depth, elevation and latitude/longitude following Prescott and Hutton (1994). Total dose rates were calculated based on water content, radioisotope concentrations, and cosmic contribution (Table 4).

4 Results

4.1 Geomorphological mapping

4.1.1 Ice marginal features - moraine complexes

We mapped and defined moraine complexes as confined areas of positive relief with curved and continuous shapes composed of moraine ridges and hummocks (Leger et al., 2020) that are separated from each other by outwash plains (Peltier et al., 2023). Moraine ridges are recognized as linear-to-curved high-relief glaciogenic landforms that exhibit a break in slope, while hummocks are subrounded to rounded mounds (Leger et al., 2020). We identified four major moraine complexes in the upper Río Santa Cruz valley (Fig. 2, S1, S2): Arroyo Verde I, Arroyo Verde II, El Tranquilo I and El Tranquilo II that indicate the former position of the Lago Argentino glacier lobe (Strelin and Malagnino, 1996, 2009).

The Arroyo Verde I moraines are located at one of the easternmost edges of the upper basin of the Río Santa Cruz, where the valley reaches its narrowest point, following a discontinuous semicircular pattern. Numerous moraine crests reach elevations

180 portion. These deposits are well-developed and reach elevations up to 400 m in the northern margin, compared to less-developed
 moraines that reach elevations below 300 m in the southern margin. Lastly, El Tranquilo II moraines are located ~ 10 km
 inboard of the El Tranquilo I moraines, separated by an extensive outwash plain in the central portion of the valley. Here, these
 moraines exhibit low-gradient and low-relief surfaces and are intersected by alluvial fans and paleochannels. They are found
 partially covered by an extensive aeolian sediments field. This moraine complex is better developed at the northern margin of
 185 the Lago Argentino, where several lateral ridges are evident, but it is less-preserved in the southern margin.

Table 2. ^{10}Be ages with 1σ internal and external uncertainties according to the different scaling schemes: LSDn (Lifton et al., 2014), St (Stone, 2000)/(Lal, 1991), and Lm (Stone, 2000)/(Lal, 1991). We report mean moraine age and standard deviation (bold), the weighted mean and standard deviation, and outliers (*).

Note that sample LA-01 (H) is not pictured in the aerial photo, but is part of the same moraine complex.

4.1.2 Subglacial features

We defined drumlinized terrains as diffused areas that contain linear features indicative of ice flow direction (Soteres et al., 2020). We identified and mapped over 600 subglacial features, including drumlins (linear depositional landforms with oval or ellipsoidal shapes) and glacial lineations (linear and narrow depositional landforms) inboard of the main moraine complexes
 190 (Leger et al., 2020), with a mean length of 372 m (Fig. 2, S2, S3). The drumlin field is extensive in the center of the valley,

particularly inboard of the El Tranquilo II moraines, where it exhibits a fan-like distribution parallel to the direction of ice flow, with a predominantly W–E orientation for the longest axis and an additional NW–SE component (Fig. S2).

4.1.3 Glaciofluvial features

We identified outwash plains as extensive low-gradient proglacial surfaces composed of sands and rounded gravels (Soteres et al., 2020), and associated them with their corresponding moraine complexes, following the framework established by Strelin and Malagnino (1996). While the Arroyo Verde glaciofluvials are located at eastern sites and at higher elevations, the El Tranquilo outwash plains are widespread in the center of the valley at elevations between 180 – 200 m with low-gradient slopes (~ 0.3 to 1 %). Notably, the El Tranquilo I outwash is located outboard of its corresponding moraine complex, whereas the El Tranquilo II outwash is found outboard of both moraine complexes. Strelin and Malagnino (1996) indicated that El Tranquilo I outwash was incised by glacial meltwater and later re-filled by El Tranquilo II outwash. Additionally, abundant paleochannels can be traced in the southern margin of the valley, following a braided pattern, as noticeable in the satellite imagery (Fig. 2, S3). Evidence of former meltwater routing was mapped as paleochannels given their sinuosity, and negative relief as well as lack of modern drainage (Leger et al., 2020).

4.1.4 Glaciolacustrine features

Glaciolacustrine landforms are mainly found in the center of the valley, outboard of El Tranquilo I moraines, which partially cover the surface of the glaciolacustrine deposits (Fig. 2). Exposed sections show deformed silt-sized sequences with thicknesses reaching up to ~ 3 m or more. Lacustrine landforms are evident in the southeastern margin of the valley in the form of paleolake shorelines, paleodeltas, and spits. The northeastern margin of the valley also exhibits lacustrine landforms, which are partially covered by moraine ridges and hummocks from the Arroyo Verde II advance. However, these are found in a lesser state of preservation compared to the ones located in the center of the valley. Additionally, we mapped raised (paleo)lacustrine deposits and their (paleo)lake shorelines as continuous landforms with linear and parallel features circling lacustrine deposits that trace former lake level surface (Leger et al., 2020). These deposits and features are found on the eastern margin of the lake and in the central part of the valley (Strelin and Malagnino, 1996).

4.1.5 Other features

We identified additional features apart from modern hydrography (major rivers, rivers, lake, fluvial landscape). We recognized alluvial fans based on their fan-like shape, while gravitational deposits were identified based on their bowl-like shape and break in slope (Leger et al., 2020). On the other hand, we mapped scarp surfaces according to their continuous break-in-slope and the sharp elevation change (Leger et al., 2020). Lastly, aeolian deposits were identified across the landscape during ground-validating fieldwork and mapped on the imagery based on their distinctive lighter colors as well as their elongated and parallel surface morphology.

4.2 Geochronological dating

4.2.1 Arroyo Verde moraines

We sampled four boulders for ¹⁰Be exposure dating from the Arroyo Verde II moraine complex (Fig. 3I–L). The lateral moraines are found at both the southern and northern margin of the Río Santa Cruz Valley, and constitute the outermost moraine sampled (Fig. 2). Ages range from 243.1 \pm 11.5 ka (AV-01) to 132.1 \pm 6.24 ka (AV-02) in the southern margin, while samples collected at the northern margin resulted in 163.6 \pm 7.85 ka (AV-03) and 163.15 \pm 7.9 ka (AV-04).

4.2.2 El Tranquilo moraines

We report a total of fourteen ¹⁰Be cosmogenic nuclide ages from both the outermost and innermost landforms from this moraine complex, El Tranquilo I and El Tranquilo II, respectively (Fig. 2). The eight boulders from El Tranquilo I moraines have ages ranging from 59.2 to 27.7 ka (Fig. 3A–H). Six samples from El Tranquilo II moraines yield a tightly clustered distribution of exposure ages, where the age range is 37.8–35.2 ka.

We sampled sections of the outwash plains for IRSL dating, obtaining four IRSL samples from El Tranquilo II outwash (Fig. 2, 5A–C). The western sample (Fig. 5A) was collected from a sandy layer within a 1–2 m thick unit of pebble and cobble sized gravels and provided an IRSL age of 29.2 \pm 4.8 ka (SCR20-OSL-03). Two samples were collected in the central portion of the valley, from an actively eroding river bank, where a lower unit of fine to coarse sands alternates with fine silts and provides an IRSL age of 50.5 \pm 6.9 ka (SCR20-OSL-01). The upper part of this section gives way to a \sim 3.5 m thick pebble to cobble size outwash deposit that has an IRSL age of 32.1 \pm 5.5 ka (SCR20-OSL-02), which is ultimately capped by \sim 0.5 m thick cobbles and silty aeolian deposits (Fig. 5B). The eastern section is a 1-m thick profile located at the southern margin of the valley (Fig. 5C). The lower part of this section is composed of coarse sands that alternate with pebble size gravels that resulted in an IRSL

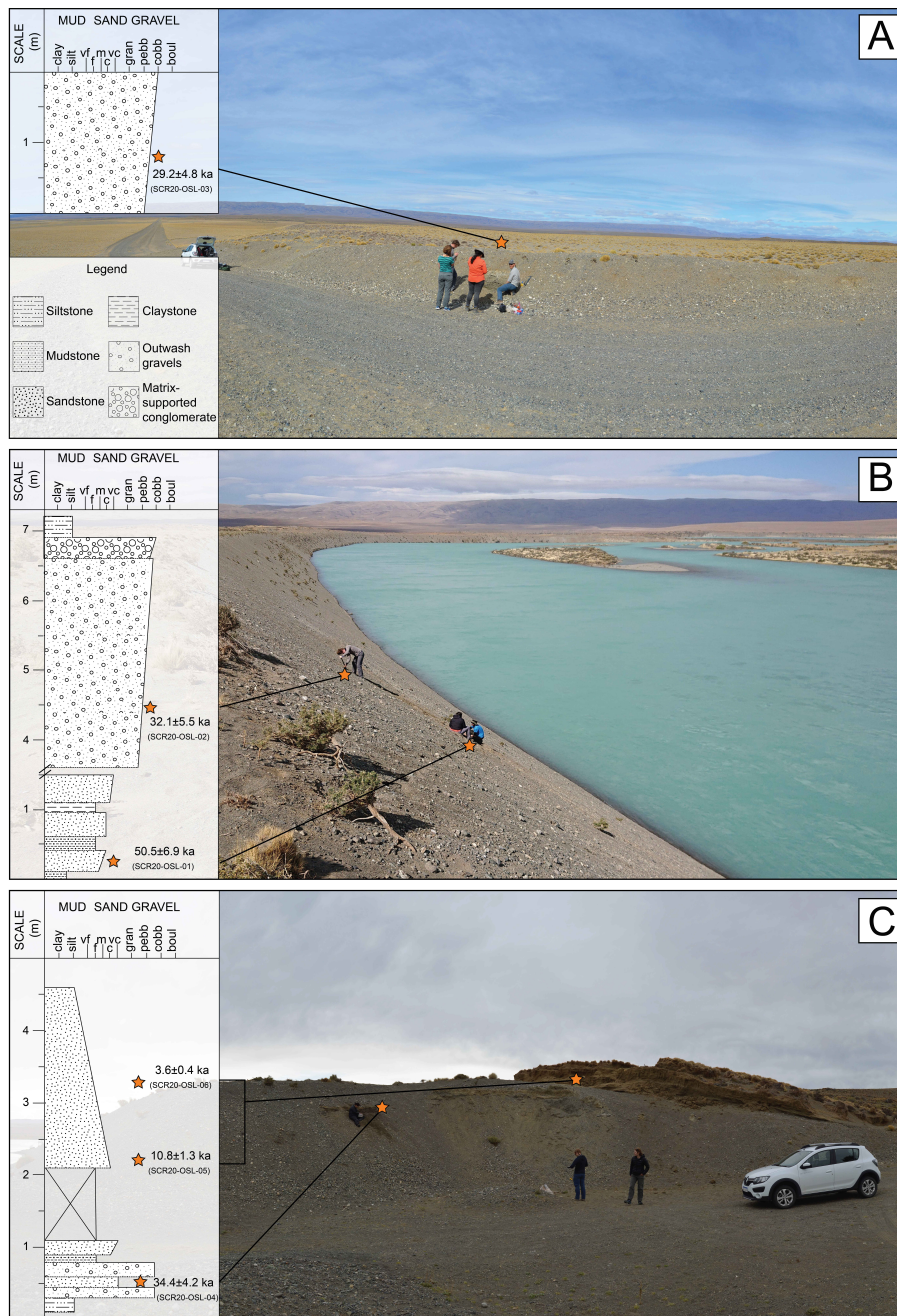

Figure 5. Field photos of outwash sediments sampled for IRSL retrieved from the El Tranquilo II outwash plains, along with their sedimentary profiles as follows: **(A)** outwash profile where the westernmost sample was collected, **(B)** aggradational sequence at the river bank where samples SCR20-OSL-01 and 02 were collected, and **(C)** easternmost section surveyed with sampled outwash and loess deposits.

¹ Assumed 5±2 % for moisture content in dose rate calculation for all samples.

² Dose rate subsamples based on grain size: fine-F (<1.7 mm), medium-M (1.7-16 mm), coarse-C (>16 mm), and weighted proportions (%) of subsamples used with chemistry in gamma dose rate calculation. Beta dose rate uses chemistry from fine fraction (<1.7 mm) only when F:>50%.

³ Radioelemental concentrations determined using ICP-MS and ICP-AES techniques; dose rate is derived from concentrations by conversion factors from Guérin et al. (2011). Grain-size based internal beta dose rate determined assuming 12.5% K and 400ppm Rb using Mejdahl (1979). Alpha contribution to dose rate determined using an efficiency factor, or 'a-value', of 0.09±0.01 after Rees-Jones (1995).

240 age of 34.4±4.2 ka (SCR20-OSL-04). The upper part of this section is characterized by a ~2.5 m unit containing well-sorted fine sands and silts sediments interpreted as aeolian deposits (loess). The lowermost loess sample yielded an IRSL of 10.8±1.3 ka (SCR20-OSL-05), while the uppermost resulted in 3.6±0.4 ka (SCR20-OSL-06).

5 Discussion

5.1 Arroyo Verde moraines chronology

245 Boulder samples from the Arroyo Verde II moraine produced a range of ages. The two boulders located on the northern margin of the valley provided similar ¹⁰Be ages (~163 ka: Fig. 3K–L). One boulder south of these provided a younger age of 132.1±6.2

ka (AV-02, Fig. 3J). On the other hand, sample AV-01, located along the southern valley margin and farther up-valley, provided the oldest age (243.1 ± 11.5 ka, Fig. 3I) of the entire dataset.

Although the three younger ages are consistent, they might not record the true age of moraine deposition, so we cannot
250 attribute the deposition of the Arroyo Verde II moraines to a particular Marine Isotope Stage. Boulders from moraine systems
older than ~ 100 ka on the Argentinian steppe are prone to yield younger ages due to exhumation during moraine degrada-
tion, sometimes underestimating the age of moraine deposition by a glacial cycle or more (Darvill et al., 2015; Hein et al.,
2009, 2011, 2017; Leger et al., 2023; Mendelová et al., 2020). These studies focused on major outlet lobes of the PIS and
showed that outwash cobbles from stable proglacial terrace surfaces provide ages closer to the true age of moraine deposition.
255 Relevant to our data set, exposure ages from cobbles obtained from stable outwash surfaces correlated to the Moreno (Lago
Buenos Aires) and Hatcher (Lago Pueyrredón) moraines revealed that they correspond to MIS 8 rather than to MIS 6, as
indicated by moraine boulders (Kaplan et al., 2005; Hein et al., 2009, 2017).

Because the above argument suggests that our boulder ages could be minimum-limiting ages on the timing of moraine
deposition, we do not exclude the age of sample AV-01 (243 ka) from our age computation. Ultimately, we speculate that this
260 moraine system could have been deposited during MIS 6 (191–130 ka; Lisiecki and Raymo, 2005), or potentially during MIS
8 (243–300 ka; Lisiecki and Raymo, 2005), given that our results range between 243 and 132 ka. Additional geochronological
work is needed to better resolve the ages of the Arroyo Verde moraines.

5.2 El Tranquilo moraines chronology

Geomorphological mapping and stratigraphy indicate that the Lago Argentino glacier expanded at least twice during the last
265 glacial cycle, with the El Tranquilo I moraines forming prior to the El Tranquilo II moraines (see section 4.1). Despite our
 ^{10}Be ages show that the El Tranquilo I and II moraines are statistically indistinguishable, our mapping indicates that they are
stratigraphically distinct. Our dataset determines that these moraines were occupied and abandoned during MIS 3, constituting
the largest preserved extent of the Argentino glacier lobe during the last glacial cycle.

While the El Tranquilo II moraines provided consistent ages, with a mean age of 36.6 ± 1.0 ka (no outliers removed), El
270 Tranquilo I moraines show a scattered distribution of ages across the moraine complex with a mean age of 39.4 ± 9.9 ka.
These moraines on the northern laterals are more developed and better preserved compared to the ones on the central portion
of the valley. Consequently, we expect boulders from the northern laterals to provide a closer age to moraine deposition
compared to boulders located in the central portion of the valley. For instance, boulders around valley center rarely exceed
half a meter in height, making these smaller boulders more susceptible to exhumation, that could result in younger ages.
275 The hummocky landforms from the central portion of the valley are heavily affected by post-depositional processes such as
aeolian erosion/deposition, landsliding, and alluvial-fan development (Fig. S4). Additionally, samples from landforms located
in the valley center could have been affected by former proglacial routes, as noted in paleochannels described in section 4.1.4.
Therefore, we exclude three ages (Table 2) that are younger than the mean age of El Tranquilo II moraines to calculate the
mean age of the El Tranquilo I, which results in 44.5 ± 8.0 ka.

280 The IRSL ages are stratigraphically consistent with the MIS 3 glaciation recorded in the cosmogenic nuclides exposure
chronology and closely complement the glacial history presented here. Based on stratigraphy and an IRSL age of ~ 50 ka
retrieved from coarse sands collected from the lower (though not the lowest) section of the river bank, we indicate that this age
represents a minimum limiting age on the timing of glacial advance and outwash deposition (Fig. 5B). Therefore, we suggest
that fluvial aggradation was underway by ~ 50 ka with the El Tranquilo I moraine abandonment occurring at 44.5 ± 8.0 ka
285 about 10 km westward. On the other hand, IRSL ages from outwash gravels (~ 34 – 29 ka, Table 3) post-date the El Tranquilo
II moraines, providing a close age of outwash abandonment, suggesting that glacier recession occurred shortly after ~ 36 ka.

Lastly, two additional IRSL ages from loess deposits capping the El Tranquilo II outwash (lower section = 10.8 ka, up-
per section = 3.6 ka) indicate sustained aeolian activity for the remainder of the Holocene; highlighting prolonged aeolian
deposition, as can be widely observed in the landscape.

290 5.3 Paleoclimate implications - Arroyo Verde moraines

Our moraine chronology (Fig. 6A) corroborates other Patagonian records of large – and sometimes maximum – glacier ad-
vances during MIS 6 and 8 (Fig. 6B). Recently, Leger et al. (2023) indicated that the Río Corcovado glacier lobe ($\sim 43^\circ$ S),
located in northeastern Patagonia, reached its maximum extent during MIS 8 between 290–245 ka, and subsequently advanced
during MIS 6 between 150–130 ka. Peltier et al. (2023) showed that the Río Ñirehuao glacier lobe ($\sim 45^\circ$ S) advanced during
295 MIS 6 at ~ 153 ka and ~ 137 ka, and potentially during MIS 8 at ~ 260 ka. In central Patagonia, MIS 8 advances have been
dated around Lago Buenos Aires ($\sim 46^\circ$ S) at ~ 265 ka (Hein et al., 2017) and around Lago Pueyrredón ($\sim 47^\circ$ S) at ~ 260 ka
(Hein et al., 2009). Hagemann et al. (2024) found increased sediment supply due to enhanced ice discharge off the coast of
Chile during MIS 6. Additionally, MIS 6 ages have been reported in other regions of the southern mid-latitudes, in the southern
Alps of New Zealand (Putnam et al., 2013) and southwest Tasmania (Kiernan et al., 2010).

300 The timing of these advances in Patagonia during both MIS 8 and MIS 6 coincides with lower mean atmospheric tempera-
tures (Jouzel et al., 2007) recorded by deuterium isotopes from Antarctic ice cores (Fig. 6F) as well as increased dust fluxes
inferred to be derived from enhanced rock-flour production due to glacial erosion (Fig. 6E; Lambert et al., 2008). Additionally,
sea salt sodium fluxes (Fig. 6D), indicative of sustained sea ice, are reported to be greater during glacial periods (Wolff et al.,
2006). According to Peltier et al. (2023), maximum glacial expansion in Patagonia should occur as both eccentricity and obliqui-
305 uity reach minimum values, which further correspond with expansive sea ice around Antarctica and a northward migration of
the Subantarctic front. While these conditions could drive and pace the expansion of the PIS over glacial cycles, glacial erosion
has been proposed to modulate the extent of the glacial advances from one glacial cycle to the next. Valley over-deepening over
glacial/interglacial timescales could lead to progressively more negative mass balance and successively less extensive advances
(Kaplan et al., 2009).

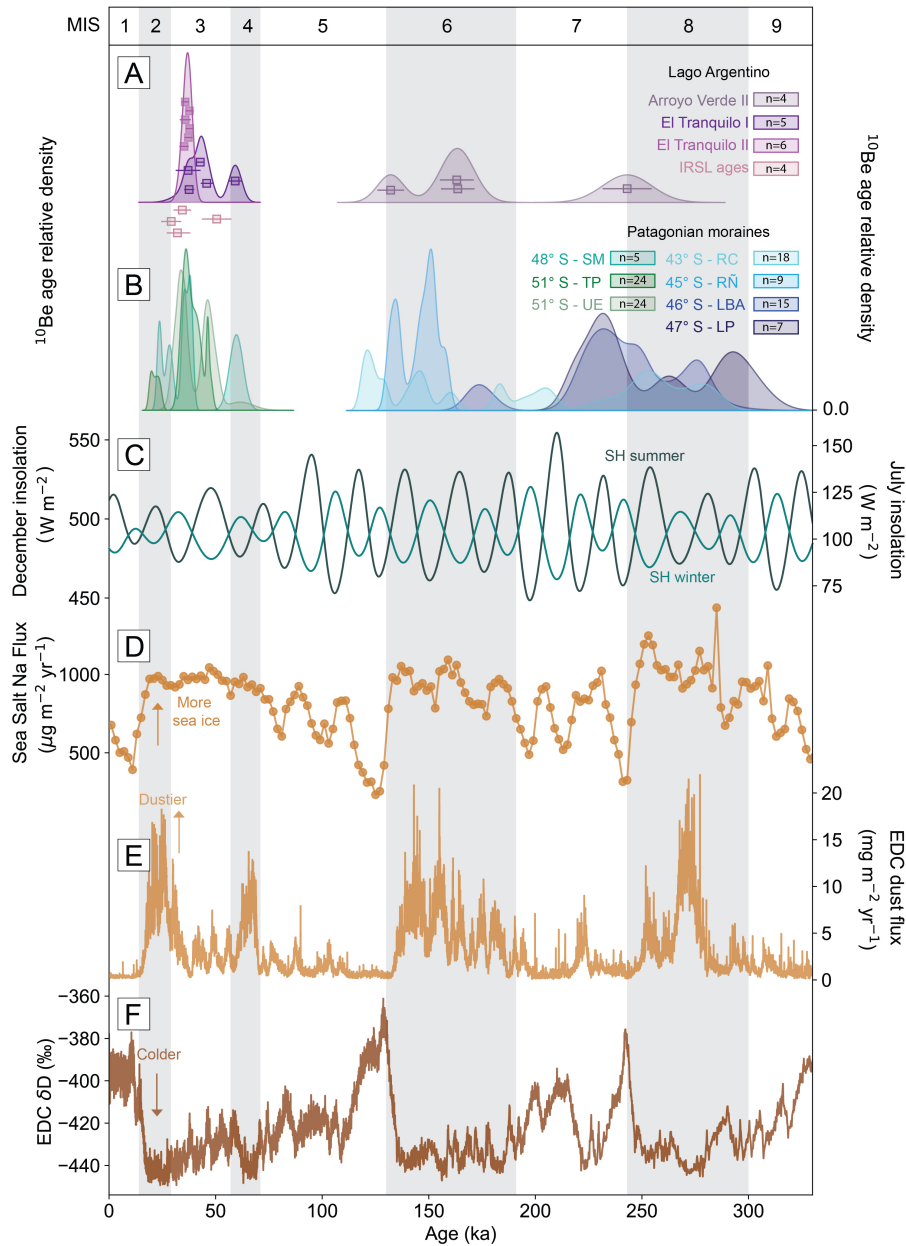

Figure 6. (A) Cosmogenic ^{10}Be and IRSL outwash ages for the Lago Argentino outlet lobe, with squares representing the individual ages along with their corresponding error. (B) Patagonian moraine age distributions from published studies mentioned in the text: Lago Buenos Aires (LBA, Hein et al., 2017), Lago Pueyrredón (LP, Hein et al., 2009), Río Corcovado (RC, Leger et al., 2023), the Río Ñirehuao (RN, Peltier et al., 2023), Lago San Martín (SM, Glasser et al., 2011), Torres del Paine (TP, García et al., 2018), and Última Esperanza (UE, García et al., 2018; Sagredo et al., 2011). (C) Summer and winter insolation values obtained for Lago Argentino (50°S) for a December average (summer) and July average (winter) after Berger and Loutre (1991). (D) Sea Salt Sodium Flux that serves as a proxy for Antarctic sea ice variability from EPICA Dome C ice core (Wolff et al., 2006). (E) Dust variability from the EPICA Dome C ice core (Lambert et al., 2008). (F) EPICA Dome C δ deuterium isotope record from the EPICA Dome C ice core (Jouzel et al., 2007) as proxy for temperature variations.

5.4.1 Comparison with other glacial records during Marine Isotope Stage 3 (MIS 3)

Our chronological and geomorphological constraints indicate that the Lago Argentino ice lobe expanded at least twice in upper Río Santa Cruz basin during MIS 3 (Fig. 6A), with fluvial aggradation underway before 50.5 ± 6.9 ka and glacial advance culminating at 44.5 ± 8.0 ka (El Tranquilo I) and at 36.6 ± 1.0 ka (El Tranquilo II). We determine that this outlet lobe reached
315 its maximum extent during MIS 3, when it deposited the El Tranquilo I and II moraines ~ 120 km away from the modern ice front, constituting the earliest and largest preserved advance of the last glacial cycle. Cross-cutting relationships, informed by El Tranquilo II outwash deposited within valleys incised into the El Tranquilo I outwash, allow us to determine that these were two different advances of the Lago Argentino glacier lobe during MIS 3.

Our new chronology for the Lago Argentino glacier lobe fits well into other evidence showing that some glaciers in the
320 southern mid-latitudes advanced during MIS 4 or 3 and were more extensive than the global LGM (MIS 2). MIS 3 glacial expansions have been widely recognized and dated across Patagonia. Radiocarbon dating on till sequences from the Chilean Lake District ($\sim 42^\circ\text{S}$), northern Patagonia, determined that glacial expansions occurred at ~ 33.6 , 30.8 ka and during early MIS 2 (Denton et al., 1999; Moreno et al., 2015). In central Patagonia, exposure ages indicated that the PIS expanded at Lago San Martín (Fig. 1B) during late MIS 3, culminating between 38–34 ka (Glasser et al., 2011), while Hein et al. (2010) dated the
325 outermost moraine of Lago Pueyrredón (Fig. 1B), providing ages ranging between ~ 32 –25 ka. Although moraine data from Lago Buenos Aires (Fig. 1B) resulted in MIS 2 ages (Douglass et al., 2006; Kaplan et al., 2004, 2005), outwash deposits dated by luminescence (Smedley et al., 2016) suggest that the proglacial plains were formed during MIS 3, between ~ 34 and 30.8 ka. In southern Patagonia, results from moraine boulders indicate that the Torres del Paine and Última Esperanza (Fig. 1B) outlet lobes expanded during MIS 3, with ice advances culminating at ~ 48 , 39, 35 ka (Çiner et al., 2022; Girault et al., 2022;
330 Sagredo et al., 2011), indicating that the MIS 2 advance was half the extent of the local LGM during MIS 3 (Fig. 6B). At Seno Skyring (Fig. 1B), Lira et al. (2022) reported full glacial conditions during MIS 2, though implying that some of the samples could reflect previous exposure from earlier glaciations, in concordance with nearby records.

In southernmost South America, Darvill et al. (2015) demonstrated that the Bahía Inútil – San Sebastián (Fig. 1B) glacier lobe advanced during MIS 3, between ~ 45.6 and 30.1 ka, while Peltier et al. (2021) reported that the Magallanes lobe advanced
335 during MIS 4, highlighting that these two lobes occupied their most extensive positions prior to the global LGM. Additionally, glacial conditions predating the global LGM have also been identified and dated in other regions of the southern mid-latitudes. For instance, a millennial-scale moraine chronology indicates that glaciers expanded from ~ 45 to 20 ka in the South Atlantic region (Mount Osborne, Hall et al., 2020) and between ~ 56 and ~ 43 ka in the sub-Antarctic Islands (Rudolph et al., 2024). Several lines of evidence support that glaciers in the southern Alps of New Zealand expanded prior to the global LGM, with
340 the most extensive advance of the last glacial cycle occurring during MIS 4 (Schaefer et al., 2015) or MIS 3 (Doughty et al., 2015; Kelley et al., 2014; Putnam et al., 2013; Shulmeister et al., 2019, 2018; Strand et al., 2019).

5.4.2 Comparison with paleoclimate records and possible drivers of glacier fluctuations

Previous studies have investigated the role of insolation in driving a pre-LGM glacier growth in the southern mid-latitudes (Fig. 6C). Huybers and Denton (2008) hypothesized that Antarctic temperatures were influenced by the duration of the seasons in the Southern Hemisphere. Winter duration was enhanced during MIS 3 relative to MIS 2, which would ultimately promote lower temperatures that were capable of driving glacier growth (Darvill et al., 2016). Additionally, southern winter insolation is thought to have played a role in driving an early MIS 3 glacier advance in Southern Patagonia, since winter insolation was at its minimum during this time ~ 48 ka, exacerbating colder winters (García et al., 2018). Lower summer insolation intensity towards late MIS 3 at ~ 35 ka, along with longer winters and reduced seasonality, would have favored ice growth during this time, coincident with some of the glacial advances in Patagonia and New Zealand (Darvill et al., 2016), including our Lago Argentino record presented here. However, these advances culminated at different times and not necessarily in a synchronous fashion, implying that insolation might not be the single forcing responsible for modulating the timing of glacier growth across the southern mid-latitudes prior to the global LGM (Darvill et al., 2015, 2016; Doughty et al., 2015; García et al., 2018; Putnam et al., 2013).

Our Lago Argentino glacial chronology suggests that ice advances culminated broadly in phase with Antarctic stadials, as evidenced in a progressive trend towards lower temperatures recorded in ice cores by lower deuterium values and higher dust fluxes at the millennial-scale during MIS 3 (Fig. 6E, F). While our record and others (Denton et al., 1999; García et al., 2018; Kelley et al., 2014; Putnam et al., 2013; Sagredo et al., 2011; Strand et al., 2019) suggest simultaneous cooling in Antarctica and the southern mid-latitudes, the timing of occurrence of glacial advances may have varied across different sites (Darvill et al., 2016). This could be explained by the fact that sea-ice formation and expansion around Antarctica was enhanced (Fig. 6D) (Fogwill et al., 2015; Sigman et al., 2004; Wolff et al., 2006) as well as ocean stratification, as evidenced in lower opal fluxes in the Southern Ocean indicative of decreased upwelling (Anderson et al., 2009). In turn, these conditions would have promoted a northward shift of the Subantarctic front, which is thought to be responsible for both a latitudinal migration and strengthening of the core of SWW belt (Kohfeld et al., 2013). This migration would have delivered increased precipitation over some zones of the southern mid-latitudes, such as at $\sim 50^\circ$ S (Lago Argentino), modulating glacier mass balance at the millennial-scale, allowing glaciers in the southern latitudes to advance earlier in the glacial cycle, such as during MIS 3 (Darvill et al., 2015, 2016; Hagemann et al., 2024; Hall et al., 2020; Herman and Brandon, 2015; Shulmeister et al., 2019; Sproson et al., 2024).

These conditions driven by feedbacks between the atmosphere–Southern–Ocean coupled system, controlled by orbital parameters, would have modulated glacial expansion of the PIS during MIS 3, with glacial erosion hotspot at $\sim 50^\circ$ S (Lago Argentino, Herman and Brandon, 2015; Sproson et al., 2024), as well as in other southern sites, between ~ 50 and ~ 40 ka (see section 5.4.1). Additionally, we suggest that sustained lower atmospheric temperatures, as well as a northward migration of the SWW belt, would have promoted widespread ice growth across Patagonia during late MIS 3, coincident with some other Patagonian lobes that experienced their local glacial maximum between ~ 35 and ~ 28 ka (see section 5.4.1). An equatorial migration of the SWW belt would have decreased precipitation over the southernmost latitudes during MIS 2, and could ex-

plain why some southern glacier lobes experienced a less extensive MIS 2 advance (Fogwill et al., 2015; Hall et al., 2020), which could be partly due to a westward migration of the ice divide (García et al., 2018; Mendelová et al., 2020; Sugden et al., 2002). This implies that moisture-starved glaciers would have not reached their prior extent, highlighting the role of increased precipitation in driving an early and extensive glacial maximum across the southern mid-latitudes (Darvill et al., 2015, 2016; 380 García et al., 2018; Rother et al., 2014; Shulmeister et al., 2019). We hypothesize that increased precipitation during MIS 3 would have been favorable for glaciers to develop a temperate regime, as indicated for some of the southernmost outlet lobes of the PIS (Darvill et al., 2017). At eastern Lago Argentino, this is evidenced in lateral meltwater channels, as well as widespread presence of drumlins and lineations inboard the moraine complexes. In turn, lower shear stresses at the glacier base favored by this thermal regime would have promoted enhanced basal sliding, allowing for glaciers to extend farther to the east.

385 5.5 Landscape evolution synthesis

The Arroyo Verde I moraines presumably indicate the easternmost glacier extent of the Lago Argentino outlet lobe at the upper basin of the Río Santa Cruz during the mid-Pleistocene (prior to 243–132 ka), where the valley reaches its narrowest point (Fig. 7A). Additional stratigraphic and glaciotectonic data indicate that the extension of this advance was topographically controlled and limited by the existing Pliocene plateaus located at the northern and southern margins of the valley (Goyanes and Massabie, 390 2015), as well as preceding west-to-east faulting (Glasser and Ghiglione, 2009). Geomorphological and chronological evidence presented here is therefore indicative that the outlet lobe did not reach elevations above the plateaus (~800–1000 m) during the Arroyo Verde glacial advances.

Glacial deposits from this advance are found in the vicinity of Río La Leona. The asymmetric nature of the morphology of the valley, which is deeper at the northern margin, as well as the orientation of the subglacial landforms, suggests that the Lago 395 Argentino lobe merged with tributary glaciers from the Guanaco, Turbio, and Viedma basins in the north and with the Río Bote tributary in the south (Strelin and Malagnino, 1996).

Strelin and Malagnino (1996) suggested that widespread glacier recession took place after the deposition of the Arroyo Verde I moraine, and pointed out that the geomorphic evidence is not conclusive of whether the following advance (i.e., Arroyo Verde II) is part of the same glaciation or not. Results from cosmogenic nuclide surface exposure dating presented here indicate that 400 the Lago Argentino lobe advanced between 243 and 132 ka, depositing the Arroyo Verde II moraines.

Later, a large proglacial lake developed, reaching elevations of ~280 masl, previously recognized as Paleolake Argentino (Strelin and Malagnino, 1996) and is represented by the glaciolacustrine sediments mapped in Fig. 2. Widespread lacustrine landforms, particularly at the southern margin of the valley, suggests that this paleolake lasted long enough in order to develop deltas, spits, and shorelines. Strelin and Malagnino (1996) suggested that this paleolake formed during the Arroyo Verde 405 II recessional phase in response to valley over-deepening (Strelin and Malagnino, 1996, 2009), where the Arroyo Verde II moraines served as a dam (Fig. 7C). Afterward, fluvial routing eroded these moraines, causing the paleolake to eventually drain. This paleolake is then thought to have been drained abruptly in response to moraine degradation by fluvial erosion (Strelin and Malagnino, 1996, 2009).

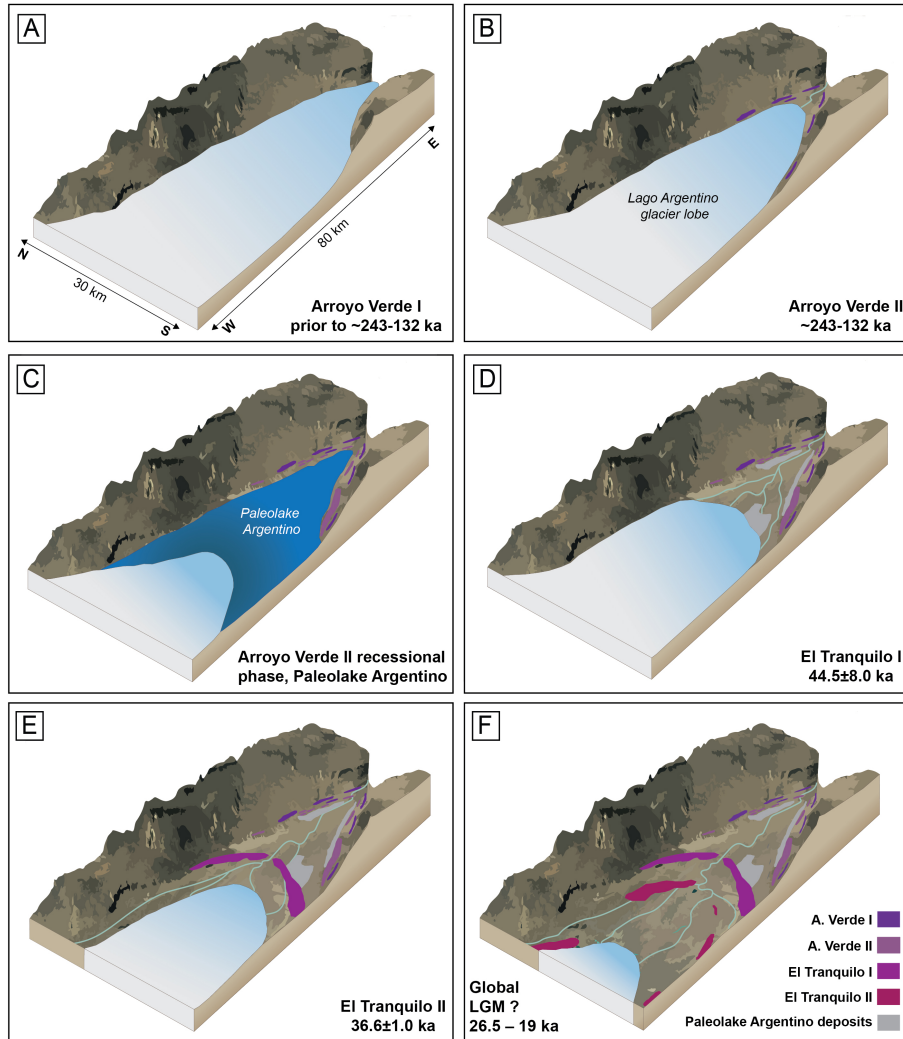

Figure 7. Landscape evolution conceptual model developed for the upper basin of the Río Santa Cruz and eastern margin of Lago Argentino, based on geochronological and geomorphological data presented here along with published interpretations (Strelin and Malagnino, 1996; Strelin et al., 1999; Strelin and Malagnino, 2009). (A) Easternmost extent of the Lago Argentino outlet lobe during the Arroyo Verde I phase prior to $\sim 243\text{--}132$ ka, (B) extent during the Arroyo Verde II phase between $\sim 243\text{--}132$ ka, (C) Arroyo Verde II recessional phase along with development of an extensive paleolake (Paleolake Argentino) likely during the Penultimate Deglaciation, (D) Extent of the Lago Argentino glacier with moraine abandonment occurring at ~ 44.5 ka (El Tranquilo I moraines), (E) Extent of the Lago Argentino glacier at ~ 36.5 ka (El Tranquilo II moraines), and (F) Recession after ~ 36.5 ka, with ice potentially present at the margin of the lake, presumably during the global LGM (26–19 ka).

Fluvial aggradation was underway by $\sim 50.5 \pm 6.9$ ka, indicating a minimum-limiting age for the following ice advance during MIS 3, while the Lago Argentino glacier lobe abandoned the El Tranquilo I moraines at $\sim 44.5 \pm 8.0$ ka (Fig. 7D). Moraine deposits from this stage were correlated with glacial deposits at higher elevations at the northern margin of the valley, suggesting that the Lago Argentino outlet lobe reached the southern part of Río La Leona valley (Strelin and Malagnino, 1996). Additionally, fault planes within deformed glaciolacustrine sediments evidence a stress transfer from the north side to the southeast, as well as a west-to-east pushing due to glacier loading (Goyanes and Massabie, 2015). The Lago Argentino glacier developed an extensive glaciofluvial plain during this stage that was later partially eroded by the El Tranquilo II outwash, resulting in the incision of the previously deposited outwash plain and filling of younger outwash (cut-and-fill).

Inboard of the El Tranquilo I moraines, the Tranquilo II moraines were deposited at $\sim 36.6 \pm 1.0$ ka during a less extensive ice advance that did not reach the Río La Leona valley, being spatially restricted to the northeastern margin of Lago Argentino (Fig. 7E). Here, paleochannels reveal that the Río La Leona drained into Río Santa Cruz as the ice occupied the eastern margins of Lago Argentino. Later, the Río La Leona changed its drainage route by draining into the lake after the ice lobe abandoned the margins of Lago Argentino (Fig. 7E) and receded westward (Strelin and Malagnino, 1996). Strelin and Malagnino (1996) indicated that during this time the lake level dropped from about 230 to 210 meters as the moraine circling Lago Argentino was subsequently eroded. While evidence of a MIS 2 advance is lacking in our terrestrial geomorphic record, we speculate that it could be deposited within the lake basin or covered by the extensive aeolian deposits located at the eastern margin of the lake (Fig. 7F). Later, widespread recession took place until the following advance occurred during the Late Glacial. This advance is recorded in the Puerto Banderas moraines, about 45 km west of the margins of Lago Argentino (Strelin et al., 2011).

Finally, we indicate that our IRSL ages document the onset of loess deposition at ~ 10.8 ka in southern Patagonia, as well as sustained aeolian activity during the Holocene. Our ages (10.8 and 3.6 ka) coincide with warm and dry intervals recorded by changes in pollen assemblages retrieved from Lago Cipreses (Moreno et al., 2018), which is located less than 100 km south of Lago Argentino. While evidence for glacial advances is available from southern Patagonia during the Holocene (García et al., 2020; Kaplan et al., 2016; Reynhout et al., 2019; Sagredo et al., 2021; Strelin et al., 2014), the paucity of glacial records at ~ 10.8 ka and ~ 3.6 ka coincides with these warm and dry periods defined by pollen assemblages (Moreno et al., 2018).

6 Conclusions

We investigate the glaciogenic landforms at the upper basin of Río Santa Cruz, eastern Lago Argentino, and we identify at least four moraine complexes (i.e., Arroyo Verde I and II; El Tranquilo I and II) through high-resolution geomorphological mapping. We use two independent geochronological techniques to provide the first published constraints on the timing of the middle-to-late Pleistocene glaciations by employing ^{10}Be cosmogenic nuclide surface exposure dating on boulders and IRSL on outwash sediments. We determine that the Lago Argentino glacier, an outlet lobe of the former Patagonian Ice Sheet, expanded between ~ 240 – 130 ka in the upper basin of the Río Santa Cruz, where it deposited the Arroyo Verde II moraines during the middle-to-late Pleistocene. Additionally, we find that fluvial aggradation due to glacier advance was underway by 50.5 ± 6.9 ka and that El Tranquilo I moraines were deposited during Marine Isotope Stage 3 at 44.5 ± 8.0 ka. This advance

precedes the global Last Glacial Maximum, and constitutes the most extensive advance of the Lago Argentino glacier during the last glacial cycle, being consistent with published records around the southern mid-latitudes. We determine that the second pulse of this advance (i.e., El Tranquilo II) culminated at 36.6 ± 1.0 ka, while proglacial plains became abandoned between
445 34–29 ka. We hypothesize that the glacier did not occupy the Río Santa Cruz upper basin during MIS 2 and likely remained limited to the margins of the modern Lago Argentino.

Based on our new chronology, we find that glacial conditions recorded in Antarctic ice cores were also present and widespread across Patagonia, both in the north and in the south. We hypothesize that the duration of the Southern Hemisphere winters along with minimum summer insolation promoted colder conditions during MIS 3. These conditions caused the Southern Westerly
450 Winds (SWW) belt to strengthen and shift latitudinally, resulting in enhanced precipitation in the southern latitudes, which in turn drove glacial expansion at Lago Argentino. Our record coincides with evidence from different glacier lobes nearby (e.g., Torres del Paine, Última Esperanza, and San Sebastián – Bahía Inútil) and highlights the role of millennial-scale fluctuations of the strength and latitudinal position of the SWW belt in modulating the mass balance of mid-latitude glaciers during the last glacial cycle. We suggest that increased precipitation would have induced a temperate regime of the Lago Argentino
455 glacier, favoring basal sliding and causing the glacier to reach its most extensive position during the last glacial cycle before MIS 2. Lastly, we document the onset of aeolian deposition after ~ 10.8 ka following warmer and drier conditions in southern Patagonia, as evidenced in pollen records nearby.

Data availability. All data associated with the production of new ^{10}Be exposure ages and IRSL ages, including field and analytical data, are provided in the manuscript tables and figures and in the supporting documents in the supplementary material. The 5 m digital elevation
460 model is available from Instituto Geográfico Nacional at <https://www.ign.gov.ar/NuestrasActividades/Geodesia/ModeloDigitalElevaciones/Introduccion>. Global bathymetry data is available from the GEBCO website at https://www.gebco.net/data_and_products/gridded_bathymetry_data. Wind speed data available from the NCEP-NCAR Reanalysis 1 at <https://psl.noaa.gov/data/gridded/data.ncep.reanalysis.html>. Outlines (ice sheet extent, rivers, lakes, and icefields) used in for Fig. 1B were adapted from the PATICE project (Davies et al., 2020). Insolation curves obtained for Lago Argentino area were derived using climlab (<https://climlab.readthedocs.io/en/latest/index.html>). Lastly, shapefiles
465 produced in this work are available at <https://doi.org/10.5281/zenodo.11556612>.

Author contributions. MR, SBP, MV, and ADW conceived the study. MR, AGJ, and SAM carried out ^{10}Be extraction. SBP and TR analyzed IRSL samples. MR generated maps with inputs from MAM and JAS. MR processed the data, and wrote the manuscript with input from all authors.

Competing interests. The authors declare no competing interests.

470 *Acknowledgements.* The authors would like to thank the owners of the sites visited who granted access, Anastasia Fedotova and Guillermo
Tamburini-Beliveau for field support, as well locals in El Calafate who provided directions and facilitated the expedition. Rock crushing
was carried out at the STAMP Lab at the University of Minnesota-Twin Cities, therefore we thank the research staff who assisted in the
process. The authors thank Dr. Michael R. Kaplan for early conversations that greatly improved the interpretation of the dataset, as well as
Dr. Phillip Larson and Dr. Victoria M. Fernandes for the insights on fluvial geomorphology. Additionally, we thank Dr. Eduardo Malagnino
475 for feedback on glacial geomorphological mapping, as well as colleagues from the GUANACO project for conversations that inspired this
work. This material is based upon work supported by the National Science Foundation under a collaborative research award Grant No. EAR-
1714614 to Wickert, Ito, and Noren, coordinated by Lead PI Maria Beatrice Magnani. Lastly, we would like to thank the editor Dr. Neil
Glasser for handling the review as well as Dr. Andrew Hein and Dr. Christopher Darvill for their insightful reviews that greatly improved
this manuscript.
