Abstract. During the Pliocene, atmospheric CO₂ concentrations (pCO₂) were similar to today’s and global average temperature was ~3 °C higher. However, the relationships and phasing between variability in climate and pCO₂ on orbital time scales are not well understood. Specifically, questions remain about the nature of a lag of pCO₂ relative to benthic foraminiferal δ¹⁸O in the late-Pliocene Marine Isotope Stage M2 (3300 kiloannum ago, ka), which was longer than during the Pleistocene. Here, we present a multi-proxy paleoceanographic reconstruction of the late-Pliocene subantarctic zone, which is today one of the major ocean sinks of atmospheric CO₂. New dinoflagellate cyst assemblage data is combined with previously published sea surface temperature reconstructions, to reveal past surface conditions, including latitudinal migrations of the subtropical front (STF) over the late-Pliocene at ODP Site 1168, offshore west Tasmania. We observe strong oceanographic variability at the STF over glacial-interglacial timescales, especially across the M2 (3320–3260 ka). By providing tight and independent age constraints from benthic foraminiferal δ¹⁸O, we find that, much more than benthic δ¹⁸O or local SST, latitudinal migrations of the STF are tightly coupled to pCO₂ variations across the M2. Specifically, a northerly position of the STF during M2 deglaciation coincides with generally low pCO₂. We postulate that the efficiency of the Southern Ocean carbon outgassing varied strongly with migrations of the STF, and that is in part accounted for the variability in pCO₂ across M2.

1 Introduction

As the largest exogenic carbon reservoir on Earth, the ocean plays a pivotal role in regulating Earth’s climate, through the balance between CO₂ uptake and outgassing (Sabine et al., 2004; Friedlingstein et al., 2022). Upwelling in the polar frontal zone flushes respired CO₂ from deep ocean into the atmosphere (Process 1 in Fig. 1a). This process is predominantly controlled by shifts in sea ice extent and westerlies over glacial and interglacial climates, which move the latitudinal position of oceanic fronts in the Southern Ocean (Toggweiler et al., 2006; Skinner et al., 2010; Rae et al., 2018). Moreover, the biological carbon pump absorbs dissolved CO₂ and removes it from surface waters via export productivity (Martin, 1990; Martínez-García et al., 2014; Thöle et al., 2019), thereby reducing surface dissolved inorganic carbon (DIC) which enhances CO₂ diffusion from the atmosphere (Process 2, 3 in Fig. 1a; Egleston et al., 2010; Gruber et al., 2023). This process mainly takes place at the boundary between the subantarctic and subtropical zone (SAZ), where ocean surface temperature (which has a negative
influence on CO₂ uptake), ocean stratification (negative), salinity (negative) and DIC (negative) determine CO₂ diffusion efficiency. The past decades have seen profound changes in sea surface temperature (SST), salinity (SSS) and the stratification of the SAZ surface waters (Sabine et al., 2004). How these processes will affect the ability of the ocean to act as climate change mitigator in the coming decades, and the amount of excess CO₂ that would consequently remain in the atmosphere is currently uncertain (Gruber et al., 2023). This creates a critical uncertainty in the projections of atmospheric CO₂ concentration (pCO₂) and the resulting effects on climate and sea level, given emission pathway scenarios (IPCC, 2019; Burton et al., 2023).

Reconstructing Southern Ocean conditions in past deglaciation phases might help in understanding interactions between atmospheric climate and ocean conditions. The late-Pliocene is marked by dominant obliquity-controlled benthic foraminiferal oxygen isotope (δ¹⁸Obf) increases that have been interpreted as glaciation/cooling phases (e.g., Tiedemann et al., 1994; Shackleton et al., 1995; Lisiecki and Raymo, 2005). The most prominent of which is the Marine Isotope Stage (MIS) M2 (3312–3264 ka; Keigwin, 1987), the deglaciation of which terminates into the mid-Piacenzian Warm Period (mPWP, 3264–3025 ka). Questions remain on its forcing, but also whether this event is mostly reflective of deep-ocean cooling or ice volume increase. Antarctic ice-proximal lithological and biomarker records suggest surface cooling and ice advance and therefore ice volume increase is involved (McKay et al., 2012; Cook et al., 2013; Patterson et al., 2014), perhaps also on the northern hemisphere as suggested by ice-rafted detritus (Flesche Kleiven et al., 2002). In contrast, bottom water temperature (BWT; Braaten et al., 2023) and ice sheet (Yamane et al., 2015; Mas e Braga et al., 2023) studies suggest limited ice volume change across M2–mPWP transition.

The subsequent mPWP is the most recent time whereby climate conditions were at times equilibrated to modern like pCO₂ of about 400 parts per million (De la Vega et al., 2020; CENCO2PIP CONSORTIUM, 2023). Specifically, MIS KM5c (3205 ka) has been a focus point of study because of the similar orbital configuration as today (Haywood et al., 2020). The Pliocene Model Intercomparison Project Phase 2 (PLIOMIP 2; Haywood et al., 2020) compares an ensemble of numerical models run under similar boundary conditions, to global compilations of proxy data from sediment cores (e.g., of sea surface temperature, SST; McClymont et al., 2020). From these efforts, accurate global average temperature, climate sensitivity to pCO₂ (2.6–4.8 °C; Haywood et al., 2020) and increased hydrological cycle (wetter equatorial regions, drier subtropical regions; Han et al., 2021) were reconstructed.

The nature and forcing factors behind the M2–mPWP glacial-interglacial transition (3320-3260 ka) is not well understood. High-resolution pCO₂ reconstructions for the late-Pliocene reveal low amplitude variability on orbital time scales (De la Vega et al., 2020), i.e., of similar magnitude as that in the late Pleistocene, but the trends in pCO₂ and δ¹⁸Obf are not as synchronous as in the Pleistocene. Specifically, while PLIOMIP2 demonstrates that overall high pCO₂ in the late-Pliocene is likely responsible for the warmer-than-modern climates (Burton et al., 2023), questions remain on the exact phase relationship between pCO₂ change and δ¹⁸Obf across the M2–mPWP transition. Available records seem to suggest that pCO₂ lags changes
in $\delta^{18}O_{bf}$ and (sub)surface cooling about 10–20 kyr (De La Vega et al., 2020; van der Weijst et al., 2022), or in any case are on these time scales not directly related through climate sensitivity to radiative forcing. We further note that collective knowledge on high-resolution $pCO_2$ change across the M2/mPWP interval is restricted to one record. Mg/Ca- and clumped isotope-based deep-sea cooling also demonstrate a lag relative to $\delta^{18}O_{bf}$ (Braaten et al., 2023). These leave the question open how $pCO_2$, ocean and cryosphere influenced each other over the M2-mPWP transition.

Here we investigate how the surface oceanography of one of the major ocean carbon sinks, the SAZ, changed through the M2-mPWP transition, and infer the implications for the carbon uptake efficiency of the region. We present a multiproxy reconstruction of paleoceanographic conditions from Ocean Drilling Program (ODP) Site 1168 (Fig. 1b), offshore west Tasmania, which is located close to the modern position of the subtropical front (STF) and the centre of the modern subantarctic/subtropical zone. We reconstruct surface ocean conditions based on dinoflagellate cyst assemblages, a microplankton group that is strongly tied to specific ocean surface conditions: SST, SSS and nutrients (Thöle et al., 2023). These strict affinities are applied together with previously published biomarker-based sea surface temperature for a detailed reconstruction of changing oceanographic conditions: the latitudinal position of the subtropical front through time, which potentially deciphers the delayed $pCO_2$ change with respect to $\delta^{18}O_{bf}$.
Figure 1: (a) Schematic view of the ocean circulation in the Southern Ocean between Antarctica and Australia. Arrows in the ocean denote southern overturning circulation (blue), mid-depth overturning circulation (red); SAMW=subantarctic mode water, AAIW=Antarctic Intermediate Water, U/LCDW=Upper/Lower Component Deep Water, AABW=Antarctic Bottom Water, ACC=Antarctic Circumpolar Current; Curvy arrows denote CO₂ uptake or outgassing processes (1. Deep ocean degassing, red; 2. Physical diffusion, spring green; 3. Biological carbon pump, green). (b) Modern site location of ODP Site 1168. Colors indicate sea surface temperatures; Contours indicates sea surface salinity; Grey blocks indicate modern coastline and sea ice extent. Purple arrows denote ocean currents (LC=Leeuwin Current, EAC=East Australia Current). Pink dashed lines denote oceanic fronts (STF=Subtropical Front, SAF=Subantarctic Front, PF=Polar Front) and zones in between (SAZ/Subtropical/Subantarctic Zone, PFZ=Polar Frontal Zone, AZ=Antarctic Zone) are mentioned in red. Data, map and visualization were generated using the Giovanni online data system (https://giovanni.gsfc.nasa.gov/giovanni/) developed and maintained by the National Aeronautics and Space Administration Goddard Earth Sciences Data and Information Services Center (Acker and Leptoukh, 2007). SST and SSS data are derived from MODIS-Aqua provided to Giovanni by the Ocean Biology Distributed Active Archive Center.
2 Materials and Methods

2.1 Study site

ODP Site 1168 (42°36.5809’S, 144°24.7620’E; 2463 meters modern water depth; Fig. 1a) was drilled on the continental slope offshore west Tasmania (Exon et al., 2001). The Pliocene part of the sequence contains greenish-grey foraminifer-bearing nannofossil ooze with significant detrital clay input (Exon et al., 2001). At present, the STF is located closely over this site, which separates warm (>17 °C), saline subtropical waters from comparably cold (<13 °C) and fresh subantarctic water masses (Heath, 1985; Exon et al., 2001). Site 1168 is characterized by a modern SST seasonality ranging from 13–17 °C (winter–summer) and a modern BWT of 2.5 °C.

2.2 Palynology

We processed 56 samples for palynology in the late-Pliocene interval. Processing used standard procedures of the GeoLab of Utrecht University (e.g., Brinkhuis et al., 2003). Briefly, this involves first spiking samples with Lycopodium clavatum spores prior to palynological processing to allow for quantification of the absolute number of dinocysts per sample (Stockmarr, 1971). Samples were then treated with 30% hydrochloric acid and ~38–40% hydrofluoric acid to concentrate the acid-resistant organic residue. The isolation of the 10-250 μm fraction was established using nylon mesh sieves and an ultrasonic bath to break up agglutinated particles of the residue. Palynomorphs were counted up to a minimum of 200 identified dinocysts if possible. Taxonomy follows that stated on palsys.org (see Bijl and Brinkhuis, 2023; last access 8-1-2024). Functional ecological dinocyst grouping follows those derived from modern assemblages (Fig. 2; Thöle et al., 2023). Notably, Nematosphaeropsis labyrinthus is characteristic for the Nlab cluster that prevails south of the STF; Impagidinium aculeatum, Operculodinium centrocarpum and Spiniferites spp. thrive in the Iacu-, high-Ocen-, and Spin- clusters to the north of the STF (Fig. 2). A STF index is then defined as South of STF/(South+North of STF) in order to quantitatively demonstrate the migration of STF, although the index does not directly indicate the latitudinal position of STF. A higher value of the index indicates that the STF is positioned relatively further north, and vice versa. There are additional dinocysts assemblages specific for Southern Ocean zones further away from the STF (Fig. 2; Thöle et al., 2023). This creates an opportunity to reconstruct in detail past changes in the latitudinal position of the STF through the late-Pliocene, and with that, the oceanographic changes in the subantarctic/subtropical carbon sink. In addition, given that Impagidinium pallidum, which is a typical bipolar cold-water species in the modern ocean (the only Impagidinium in the ice-proximal Sant cluster, Fig. 2a), seems to have an ambiguous paleo-affinity (De Schepper et al., 2011) and generally low abundance and widespread occurrence in the modern Southern Ocean (Thöle et al., 2023), it is not separated from the other Impagidinium in the grouping. Moreover, because the latitudinal position of the STF is representative of the oceanographic fronts associated with ACC and has implications for the sea ice extent further south, our reconstructions also have implications for the ability of the polar frontal zone to emit CO2 to the atmosphere.
Figure 2: (a). Schematic representation of the generalized biogeographic distribution of dinocysts in Southern Ocean surface sediments. Pies represent average assemblage composition of the nine clusters described in this paper. Position of these pies represent their typical latitudinal band of occurrence. Also plotted are the frontal systems (blue lines, STF = Subtropical Front, SAF = Subantarctic Front, PF = Polar Front). The Subantarctic Zone (SAZ) is the water mass between the STF and PF. (b) Comparison of sea surface temperature and sea surface salinity in different clusters for the 9-cluster solution of the sh_655 data set. The median, 25% – 75% quantiles and 95% confidence interval are indicated by the black line, boxes and whiskers, respectively. Modified from Thöle et al. (2023).

2.3 Benthic foraminiferal stable isotopes

Each sediment sample was freeze-dried, washed over a 63 μm sieve, oven-dried at 50 °C and then dry-sieved into different size fractions. We mainly picked tests of Cibicidoides mundulus from the 250–355 μm size fraction for our measurements. The picked specimens were cracked between two glass plates after which the test fragments were ultrasonicated in deionized water (3*30 s) to remove adhering sediment, organic lining and nannofossils. The test fragments were dried at room temperature overnight. In order to obtain enough material, other benthic species are also processed. We use Cibicidoides mundulus and Cibicidoides (Planulina) wuellerstorfi for both stable carbon and oxygen.

Stable isotope measurements were performed using a Thermo Scientific MAT 253 Plus and a Thermo Scientific MAT 253 mass spectrometer at the GeoLab of Utrecht University. Both mass spectrometers were coupled to Thermo Fisher Scientific
Kiel IV carbonate preparation devices. CO₂ gas was extracted from carbonate samples with phosphoric acid at a reaction temperature of 70°C. Since both instruments are equipped for clumped isotope analysis, a Porapak trap included in each Kiel IV carbonate preparation system was kept at -40°C to remove organic contaminants from the sample gas. Between each run, the Porapak trap was heated at 120°C for at least 1 h for cleaning. Every measurement run included a similar number of samples and carbonate standards (Kocken et al., 2019). 3 carbonate standards (ETH-1, 2, 3). Two additional reference standards (IAEA-C2 and Merck) were measured in each run to monitor the long-term reproducibility and stability of the instrument. The δ¹³C and δ¹⁸O values (reported relative to the Vienna Pee Dee Belemnite (VPDB) scale) of IAEA-C2 showed an external reproducibility (standard deviation) of 0.06 ‰ and 0.06 ‰, respectively.

2.4 Bulk carbonate stable isotopes

Bulk carbonate isotopes were measured as additional stratigraphic tool alongside the benthic δ¹³C and δ¹⁸O. For 118 samples, between 50–100 μg of powdered sediment was analysed on a Thermo Finnigan GasBench II system, coupled to a Thermo Delta-V mass spectrometer. Homogenized samples were transferred to sealable vials which were flushed with helium for 5 minutes per vial, to remove atmospheric oxygen and carbon. In each run, 65 samples were then treated with H₃PO₄ at a temperature of 72°C together with carbonate standards NAXOS (11 times) and IAEA-603 (4 times) for the purpose of calibration. All isotope values are reported against VPDB. Analytical precision, as determined by the SD of NAXOS was better than 0.08‰ for δ¹⁸O and 0.04‰ δ¹³C.

3 Results

3.1 Stable isotopes and age model

The post-expedition age model of sediments from ODP Site 1168 comprises of biostratigraphic constraints from nannofossils, foraminifera, diatoms and dinoflagellate cysts, paleomagnetic constraints, and for the Pleistocene identifications of marine isotope stages from benthic foraminiferal isotopes (Stickley et al., 2004). For the Pliocene-Pleistocene part of the record, the paleomagnetic constraints, which come from Hole B, are structurally offset by around 50m/1 million years from biostratigraphic datums and Pleistocene marine isotope stages that come from Hole A, even at splice depth (see Stickley et al., 2004). For a high-resolution age model of the late-Pliocene section at Hole 1168A, we generated new benthic foraminiferal and bulk carbonate stable isotope data across the suspected late-Pliocene interval and compared these to the shipboard colour reflectance data (Exon et al., 2001). Cyclicity in both were then compared to orbital cycles seen in the CENOGRID (Westerhold et al., 2020) and LR04 benthic foraminifer oxygen isotope stack (Lisiecki and Raymo, 2005) (Fig. 3). Since all our new data and the stratigraphic constraints except the paleomagnetic reversals derive from Hole A, we decided for the purpose of this study to ignore the offset paleomagnetic constraints from Hole B (as published in Stickley et al. (2004) and updated in Hou et al. (2023a)) for now, and recommend that later studies should first revisit the composite depth, stratigraphic correlation and quality of the magnetic data before including these into the composite age model of the site.
New $\delta^{18}$O$_{bf}$ and $\delta^{18}$O$_{bulk}$ between 27–40 meter below sea floor (mbsf) correlates well with colour reflectance, whereby low/high $\delta^{18}$O correlates to high/low lightness of the sediment (Fig. 3). Both show a conspicuous trough at 35.0–35.5 mbsf, and based on the available biostratigraphic age model constraints, we interpret that to reflect the MIS M2. Tuning the resulting $\delta^{18}$O$_{bf}$ and colour reflectance record (Exon et al., 2001) to the CENOGRID and LR04 global stacks (Lisiecki and Raymo, 2005; Westerhold et al., 2020) resulted in 4 solid age tie points and confidence in the stratigraphic position of the M2 isotope excursion. A maximum in $\delta^{18}$O$_{bulk}$ at 30 mbsf is tuned to MIS G20. Additional 2 stratigraphic tie points were chosen by tuning the colour reflectance record to CENOGRID/LR04 stack further up and down-section. See Table 1 for the stratigraphic tie points in this paper, and the resulting age model.

3.2 Sea surface temperature

SST records of the Pliocene Site 1168 have been previously published (Hou et al., 2023a). SST proxies, $U^k_{37}$ and TEX$_{86}$, were calculated based on alkenones and Glycerol Dialkyl Glycerol Tetraethers (GDGTs) respectively. $U^k_{37}$-based SSTs vary around 17 °C prior to M2. They decrease to 12°C at the peak of the M2 glaciation (Fig. 4a). In the mPWP, SST varies around 14 °C, which is approximately 2°C lower than the pre-M2 interval (Fig. 4a). Additionally, SST at KM5c yields 14.5 °C. TEX$_{86}$-based SSTs in general resemble those derived from $U^k_{37}$, however, the amplitude of cooling at M2 is 3°C higher, which we cannot ascribe to confounding factors in TEX$_{86}$: GDGT-2/GDGT-3 ratios, a general indicator for additional deep-water contributions to TEX$_{86}$ (Taylor et al., 2013; Ho and Laepple, 2016; van der Weijst et al., 2022), do not change across the M2 phase.

3.3 Dinocyst assemblage

Pliocene dinocyst assemblages at Site 1168 are broadly similar to modern assemblages around the subtropical front, thus enable us to use the information of modern affinities of these species (Thöle et al., 2023) to reconstruct paleoceanographic conditions at this site. Prior to 3400 ka, the STF index is about 0.3 and assemblages are typical for modern regions north of the STF (Fig.
With abundant *O. centrocarpum* (High-Ocen-cluster), *I. aculeatum* (Iacu cluster) and *Spiniferites* spp (Spin-cluster; Thöle et al., 2023). The increase of *N. labyrinthus* (around 3400 ka) makes the assemblages progressively more similar to those of the SAZ, south of the STF and forms the Nlab-cluster when it is dominant in the assemblage (>40%). The attendance of *I. pallidum* is sporadic throughout the record, however, transiently increases to ~10% at 3300ka and dominates the other *Impagidinium* group (see raw data). The abundance of *N. labyrinthus* peaks at 3275 ka and the STF index reaches 0.8, well after the peak of the M2, in the M2 deglaciation stage (Fig. 4b). Thereafter, north-of-STF assemblages recovered and replaced *N. labyrinthus* in the mPWP.
4 Discussion

4.1 STF migrations and SAZ surface conditions in the late Pliocene

Lowest local SSTs (13 °C based on U^k^37) were recorded at peak M2 glaciation: ~6 °C lower than those before M2 and ~5°C lower than those in the mPWP (Fig. 4a). The amplitude of the SST variation over the mPWP glacial-interglacial cycles is about 1–2 °C, much smaller than the cooling associated with M2. In terms of the cooling amplitude, SSTs in low–mid latitudes during M2 suggest that it represents an unusual strong glacial (Lawrence et al., 2009; De Schepper et al., 2013; Liu et al., 2019, 2022; van der Weijst et al., 2022). However, SST reconstructions from high latitude surface (Risebrobakken et al., 2016; Bachem et al., 2017) and deep ocean (Braaten et al., 2023) suggest that either the M2 indicates no profound cooling, or the cooling has similar amplitude as other glacial phases within the mPWP. The extreme SST response to M2 in the subantarctic zone is therefore extraordinary, and perhaps not the result of radiative forcing but amplified by regional or local oceanographic changes. Furthermore, SSTs of Site 1168 are highly consistent with the subsurface temperature of Site 959 recording South Atlantic Central Water, which derives from the Southern Hemisphere subtropical surface ocean (SACW, van der Weijst et al., 2022). Therefore, their similarity to surface temperatures at Site 1168 is not surprising.

The dinocyst assemblages indicate that the most northern position of the STF is reached during the M2-mPWP transition, i.e. when SST at ODP Site 1168 increased over 5 °C (Fig. 4a, b). Both peak M2 and M2 deglaciation SSTs at 1168 are within the modern SST range of Nlab-cluster (Fig. 2), although the 15–17 °C (both proxies) at deglaciation does approach the upper limit of the SST range of Nlab-cluster (Fig. 2b; Thöle et al., 2023). Based on the modern dinocyst distributions (Fig. 2b), and in particular the proliferation of N. labyrinthus (Fig. 4b), the surface ocean became ~1.5 psu fresher during the M2 deglaciation. Since there is no evidence in the palynological slides nor in GDGT-based indices (Hou et al., 2023a) for enhanced terrestrial input from runoff, we conclude that the surface ocean freshening of the subantarctic zone at M2 deglaciation originated from excessive iceberg discharge, which melted in the SAZ.
Overall, according to the changes we observed in dinocyst assemblages, we estimate that the STF was positioned to the south of Site 1168 from prior to M2 until its onset; the STF moved northward as SST decreased and *N.labyrinthus* increased during M2; During the recovery of M2, the STF moved further northward and approached the margin of Tasmania (42°S) at 3275 ka, and surface waters strongly freshened. During the mPWP, the surface salinity at Site 1168 normalized and the STF shifted poleward to a similar position as before M2.

### 4.2 Southern Ocean carbon outgassing as pCO$_2$ regulator across M2

By comparing our reconstructed STF migrations with the available pCO$_2$ reconstructions across the M2 event, we note a coincidence in phase, much stronger than with SST or benthic δ$^{18}$O changes (that do correlate well with each other). In other words, frontal shifts and pCO$_2$ lag SST and benthic δ$^{18}$O across M2. The bulk of the late Pliocene pCO$_2$ record is generated from ODP Site 999, of which the surface air-sea disequilibrium for CO$_2$ is close to 0 (Martínez-Botí et al., 2015). Thus, this Caribbean Sea site has been frequently used to reconstruct global past pCO$_2$ (Foster, 2008; Chalk et al., 2017; De la Vega et al., 2020, 2023).

At the onset of M2, pCO$_2$ was about 400 ppm (De la Vega et al., 2020) and Site 1168 had an abundance of *warm species* suggesting a southerly position of the STF. Following this maximum, the STF was moving northwards during the M2 δ$^{18}$O peak and the coolest SSTs (Fig. 4a). However, The STF reached its northernmost position at the deglaciation phase of M2 event, and this corresponds to the lowest pCO$_2$ (Fig. 4c). During the mPWP, when SST was high, the STF migrated back southward and pCO$_2$ gradually increased to ~400 ppm. We deduce from this correlation that the oceanographic changes in the SAZ influenced the ocean uptake efficiency of atmospheric carbon, which had an effect on pCO$_2$, but that this occurred out of phase with the temperature and benthic δ$^{18}$O changes. The mechanism we propose involves the ocean as source and sink of atmospheric CO$_2$ and the shifting fronts and sea ice.

The migrations of the STF in the Tasmanian sector are the consequences of the shifts in westerlies and Antarctic-proximal sea ice extent – in the Pleistocene and Miocene (Groeneveld et al., 2017; Kohfeld and Chase, 2017; Hou et al., 2023b) but also in the Pliocene. During the M2, the STF gradually shifted northward, indicating an equivalent shift of the westerlies and a northward expansion of the subantarctic zone. The northward migration of the westerlies and fronts enhanced the stratification of the Southern Ocean and thereby prevented respired CO$_2$ from outgassing into the atmosphere. Consequently, pCO$_2$ dropped, in phase with the northward migration of the STF. At the same time, the freshening of the surface SAZ (Fig. 1) must have lowered carbon uptake in the surface ocean (Bourgeois et al., 2022). However, the decreased pCO$_2$ apparently suggests that the lowered surface carbon uptake did not compensate for the reduction of emission induced by the expanding sea ice cover in the polar frontal zone. The equatorward shift of the STF, which continued into the deglaciation stage of the M2, was associated with expanded sea ice cover in the polar frontal zone, especially in the deglaciation stage, when surface waters
freshened. The higher amplitude of obliquity increased Antarctic summer insolation after M2 peak glacial advance (Fig. 4a) and this probably enhanced iceberg calving, which stimulated the northward migration and freshening of STF. Furthermore, Antarctic ice sheet simulations suggest that insolation-driven sub-shelf melting can be linked to changes in the carbon cycle (De Boer et al., 2014). Indeed, massive iceberg calving was noticed at the east Antarctic margin during deglacials in the Pliocene, associated with maximum iceberg-rafted debris (Cook et al., 2013; Patterson et al., 2014), which is in line with our frontal migration record.

When the M2 deglaciation was complete, in the mPWP, iceberg discharge ceased (Patterson et al., 2014) because in the sector of Antarctica nearest to our site fewer glaciers terminated in the ocean (Cook et al., 2013), sea ice cover decreased (Patterson et al., 2014), and westerlies moved southward. As such, the patterns in sea ice cover over the polar front controlled air-sea gas exchange: the weaker the sea ice cover, the less stratification, the more CO\textsubscript{2} outgassing from the CO\textsubscript{2}-rich deep water. Similar mechanisms, involving sea ice cover as regulator for Southern Ocean air-sea CO\textsubscript{2} exchange, have been proposed for the Pleistocene and Quaternary (Sigman et al., 2010; Kohfeld and Chase, 2017). Furthermore, the dinocyst-based, poleward positioned STF in the mPWP lies in line with simulated weak stratification and enhanced outgassing in the Southern Ocean (Zhang et al., 2013), which resulted in elevated pCO\textsubscript{2}. However, new PlioMIP2 models yield contradictory results (Weiffenbach et al., 2023). Simulations on the Southern Ocean thus are highly model dependent (Zhang et al., 2021; Weiffenbach et al., 2023). In any case, present models are not able to resolve frontal migrations or local effects due to their spatial resolution.

Nevertheless, pCO\textsubscript{2} in the Pleistocene (Bereiter et al., 2015; Yan et al., 2019) does not show lags between surface oceanography and benthic δ\textsuperscript{18}O changes (Lisiecki and Raymo, 2005; Martínez-Garcia et al., 2010; Chalk et al., 2017) as much as the M2-mPWP interval shows here. Shifts in westerlies further drove variations of dust input to the Pleistocene ocean (Abell et al., 2021) and influenced CO\textsubscript{2} uptake through the biological carbon pump (Thöle et al., 2019). Essentially, its impact on carbon storage was in phase with deep ocean CO\textsubscript{2} degassing, e.g., inducing lower pCO\textsubscript{2} in the Pleistocene glacial maxima (Ziegler et al., 2013; Ai et al., 2020). However, late-Pliocene aeolian input was limited both regionally in the Southern Ocean (Martínez-Garcia et al., 2010; Naafs et al., 2012) and globally (Teruel et al., 2021), and therefore this process played a less important role during the Pliocene. M2 glaciation occurred mainly as orbital-forced ice buildup and did not seem to have been triggered by a decline in pCO\textsubscript{2} (De la Vega et al., 2020). A new study of Δ\textsuperscript{17}N-based BWTs in the north Atlantic and north Pacific has found that deep sea cooling lags the positive δ\textsuperscript{18}O excursion of M2 by ~20kyrs (Fig. 4d; e; Braaten et al., 2023), but is in phase with the pCO\textsubscript{2} variations (De la Vega et al., 2020). Therefore, moderate changes in Pliocene pCO\textsubscript{2} across the M2 were independent of global ice volume change but instead linked to oceanographic changes (including deep ocean temperature) through the pCO\textsubscript{2}-global climate positive feedback (Braaten et al., 2023).
5 Conclusions

Our new Pliocene dinocyst assemblage data combined with previously published SSTs from the same site shed new light on the dynamics of Southern Ocean frontal systems, in relation to ice sheet and sea ice. We reconstruct that the STF migrated substantially across the M2–mPWP climatic transition. Vast sea ice extent and iceberg discharge during the deglaciation stage of M2 pushed the STF to its northernmost position, freshened it, and prevented respired CO₂ emissions from the deep ocean to the atmosphere. This suggests that, across the M2 event, Southern Ocean frontal migrations controlled ocean-air CO₂ exchange and resulted in the ρCO₂ changes on orbital timescales.

Data availability

The new palynological and benthic and bulk stable isotope data from Site 1168 are deposited at Zenodo https://doi.org/10.5281/zenodo.11086278. All other data presented have been deposited already, and references to those repository items can be found in the respective publications.

Author contributions

PKB designed the research. SH and LT processed and analysed samples for palynology, SH and PKB interpreted the palynological results. SH and MvdL washed and picked benthic foraminifera and generated the stable and clumped isotopes data. FR measured the bulk carbonate isotopes. SH, LJL and PKB refined the age model. SH wrote the paper with input from PKB, LJL and MZ. All authors have contributed to the submitted manuscript.

Acknowledgements

We thank Mariska Hoorweg, Natasja Welters, Giovanni Dammers, Desmond Eefting and Arnold van Dijk for laboratory assistance. We thank IODP and scientists of ODP Leg 189, and technicians at KCC in Kochi, Japan for making samples and data available. We are grateful to Lena Thöle, Julia Weiffenbach and Anna Braaten for discussions, and the latter also for providing revised clumped isotope data. This research is funded by ERC Starting Grant 802835 to Peter K. Bijl.
